

Every negative control's excess is predicted by its baseline imbalance

$r = 0.92$, $p = 0.008$. At perfect baseline balance the predicted hazard ratio is 0.79 (0.28–2.23).

The seizure outcome sits at baseline ratio 1 by construction, because prior seizure was an exclusion. It lies far above the line the negative controls trace, which is the argument that its elevation is not the same bias.
