

Each negative control's excess is predicted by its baseline imbalance

$r = 0.92$ (0.45 to 0.99), $p = 0.008$. At baseline balance the predicted hazard ratio is 0.79 (0.28 to 2.23).

Prior seizure was an exclusion, so the seizure outcome sits at a baseline ratio of exactly 1. Its estimate lies far outside the range the controls predict there, which is the argument that it is not the same bias.
