

Seizure and epilepsy after idiopathic intracranial hypertension

Left: risk of a first seizure. Right: among those who had one, how many had recurrent disease.

Left panel: abstracted primary outcome, full cohort, symmetric 180-day washout, exact binomial intervals. Right panel: outcome-positive patients only. Epilepsy = 2+ coded seizures 30+ days apart, OR an epilepsy-specific G40/345 code or established-disease descriptor, OR antiseizure medication continued 180+ days; ascertained to last attended encounter, not to the seizure, since recurrence occurs after the first event. The control proportion is shown in grey because it is NOT comparable to the IIH proportion: 63 of 64 outcome-positive controls carry an epilepsy-specific code, consistent with the control outcome having required stronger evidence before it was called. Topiramate, gabapentin and clobazam are excluded from the medication channel, being IIH and pain therapies rather than seizure-specific.
